Abstract

Background
Gluteal intramuscular injection of octreotide LAR is effective for control of carcinoid syndrome and delay tumor growth in midgut carcinoid tumors. However, many intended gluteal intramuscular injections are delivered subcutaneously which may lead to altered pharmacokinetics and suboptimal therapeutic outcome. We examine gender related issues in gluteal intramuscular injection.

Methods
Patients receiving intramuscular injection of octreotide LAR at the Gastrointestinal Center, University of Texas M. D. Anderson Cancer center were identified. Pelvic CTs were reviewed for evaluation of injection success and measurement of injection depth, skin to muscle depth.

Results
251 intended intramuscular injections between 12/21/2005 and 6/25/2008 were evaluable by CT. Among these, 119 (47%) were given to males; 132 (53%) were given to females. 105 (42%) were associated with subcutaneous nodules indicating subcutaneous placement; 146 (58%) were deemed successful intramuscular injection. Successful intramuscular injection rate was lower in females (42% vs 78%; P=0.001). Female had lower BMI (mean, 26.6 vs 28.8; P=0.008), but greater skin to muscle depth at optimal injection site (mean, 34 vs 24 mm; P=0.001). BMI correlated linearly with skin to muscle depth (P=0.001).

Conclusion
Gluteal intramuscular injection is more difficult in females due to greater skin to muscle distance despite lower BMI. Increased nursing education and introduction of longer needle are needed.

Background
Injection related subcutaneous nodules are commonly observed on pelvic CTs among patients receiving octreotide LAR. This suggest many such intended gluteal intramuscular (IM) injections are delivered subcutaneously.

Objective
- Evaluate gluteal IM injection success rate among patients receiving octreotide LAR
- Evaluate gender related factors associated with successful gluteal IM injection

Methods
- Gender, height, weight, body mass index (BMI) were collected from patients receiving octreotide LAR injection
- Pelvic CTs were reviewed for evaluation of injection success.
- CT measurement of injection depth, and skin to muscle depth were performed
- CT measurements of bony landmarks were performed
- CT evaluator also gave inference to reason for any miss: too cranial, lateral, caudal, and insufficient needle length.

Results
251 intended intramuscular injections between 12/21/2005 and 6/25/2008 reviewed
- 119 (47%) given to males
- 132 (53%) given to females
- 105 (42%) were subcutaneous
- 146 (58%) were intramuscular
- Male patients had fewer subcutaneous injection nodules than female patients
- Female had lower BMI
  - mean, 26.6 vs 28.8; P=0.008
- Female had greater skin to muscle depth at optimal injection site
  - mean, 34 vs 24 mm; P=0.001
- BMI correlated linearly with skin to muscle depth (P=0.001)

Skin to muscle depth greater at similar BMI

Nursing experience and IM success rate

Self-reported parameter | IM success rate | P* | Experience with IM injection | Female | Male | Comfort with LAR injection (scale 1–10) | Female | Male | Comfort with LAR injection (scale 1–10) | Female | Male |

</table>

Conclusion
- Gluteal intramuscular injections are more difficult in females due to greater skin to muscle distance despite lower BMI when compared to males.
- This is also effected by the self reported comfort levels and experience by the nurses. Increased nursing education is needed.
- Introduction of longer needles are needed to produce a higher percentage of successful intramuscular injections.
